Abstract. We study the query evaluation problem in probabilistic databases in the presence of probabilistic existential rules. Our focus is on the Datalog\(^+\) family of languages for which we define the probabilistic counterpart using a flexible and compact encoding of probabilities. This formalism can be viewed as a generalization of probabilistic databases, as it allows to generate new facts from the given ones, using so-called tuple-generating dependencies, or existential rules. We study the computational cost of this additional expressiveness under two different semantics. First, we use a conventional approach and assume that the probabilistic knowledge base is consistent and employ the standard possible world semantics. Thereafter, we introduce a probabilistic inconsistency-tolerant semantics, which we call inconsistency-tolerant possible world semantics. For both of these cases, we provide a thorough complexity analysis relative to different languages, drawing a complete picture of the complexity of probabilistic query answering in this family.

1 INTRODUCTION

Recent years have led to a significant increase in the number of application domains that generate large volumes of uncertain data. This has paved the way for a number of systems tailored towards such domains; most notably for large knowledge bases: Yago [22], Nell [31], DeepDive [36], Google’s Knowledge Vault [17], and Microsoft’s Probase [42] are systems containing a large amount of uncertain data. These systems are substantially based on the foundations of probabilistic databases (PDBs) [37]. Arguably, PDBs provide the state-of-the-art means for modeling, storing, and processing data in the presence of uncertainty.

Enriching databases with ontological knowledge is a common paradigm [33], as it allows one to deduce facts that are not explicitly specified in the database. The most widely studied languages for achieving such sophisticated data access are based on description logics (DLs) [2] and existential rules [9, 8]. Following this tradition, we study probabilistic query entailment under existential rules (tuple-generating dependencies) relative to a database. We focus on a particular family of existential rule languages, which is also referred to as Datalog\(^+\) [9, 8].

Our framework is rather general: We assume a set of probabilistic events and annotate the facts and the rules with a Boolean expression formed over these events, which we call contexts. This context-based abstraction allows a compact specification of a probability distribution over the knowledge base. Similar approaches have been used in knowledge representation [32] and are also related to data provenance and lineage [23, 32, 37] in PDBs.

The most common semantics for PDBs is the possible world semantics: a PDB factorizes into a set of possible worlds, i.e., classical databases, each of which is then associated with a probability. This semantics is also used in probabilistic logic programming (see, e.g., ProbLog [16]) and is closely related to Poole’s independent choice logic [34]. We first study probabilistic query entailment in Datalog\(^+\) under this semantics with a conventional assumption, i.e., the assumption that the probabilistic knowledge base is consistent.

Datalog\(^+\) programs can clearly lead to inconsistencies, as negative constraints, such as \(\forall x \, P(x) \land R(x) \rightarrow \bot\), are part of these programs. The obvious question is, of course, whether forcing the consistency assumption is always feasible? We answer this question negatively: PDBs are typically constructed in an automated manner; therewith, it is not easy to control which tuple is to be added to the database next. Suppose, e.g., that both atoms \(P(u)\) and \(R(u)\) are obtained with a positive probability. Clearly, adding both atoms would lead to an inconsistency, as the disjointness imposed by the rule will then be invalid; i.e., we either throw away one of these atoms, or the whole knowledge base becomes inconsistent.

One way of tackling this problem is to simply ignore the inconsistent worlds imposed by the knowledge base, and as such, to slightly change the possible world semantics to only consider consistent worlds. We argue that this is not a solution to the problem, but rather a patch, and show that considering only consistent worlds could lead to loss of valuable information. In other words, inconsistent worlds may produce meaningful answers that are lost, as they can not be captured with an adequate semantics. Thus, to retrieve as much valuable information as possible, we base ourselves on the foundations of inconsistency-tolerant reasoning, which is well-understood both in the context of DLs [26, 5, 6] and Datalog\(^+\) [28, 29, 27]. A well-known approach in inconsistency-tolerant reasoning is based on repairing the knowledge base by minimally removing some facts. As there can be many different minimal repairs (see the example above), the safe consequences are considered to be those that follow from every possible repair. In this paper, we adopt the generalized repair (GR) semantics from a recent work [18], which allows repairs both on the database and on the program. Based on the GR semantics, we define the inconsistency-tolerant possible world semantics.

For both semantic approaches, we provide a through complexity analysis relative to different existential rule languages, drawing a complete picture of the complexity of probabilistic query entailment in Datalog\(^+\). The most central class for our complexity analysis is the class PP [20], which we describe in detail. Briefly stated, our results show an analogous behavior to the classical case, i.e., moving to inconsistency-tolerant semantics can put the complexity of reasoning one level higher in the respective hierarchy.

2 MOTIVATION AND BACKGROUND

We enrich databases with ontological knowledge allowing to access probabilistic data over a logical abstraction. We concentrate on existential rule languages, also known as tuple-generating dependencies.

2.1 Existential Rules and Datalog

We recall some basics on existential rules from the context of Datalog+[9, 8] and briefly introduce conjunctive query answering under existential rules.

General. Consider (possibly infinite) mutually disjoint sets R of predicates, C of constants, V of variables, and N of nulls. A term t is a constant, a null, or a variable. An atom is an expression of the form P(t₁,...,tₙ), where P is an n-ary predicate, and t₁,...,tₙ are terms. A variable-free atom does not contain any variables as terms, and a ground atom is an atom that contains only constants as terms. An instance I is a (possibly infinite) set of variable-free atoms.

A database D is a finite set of ground atoms.

Programs. A tuple-generating dependency (TGD) (or existential rule) σ is a first-order formula Q → ∃y P(x,y), where x,y ∈ V, P(x,y) is a conjunction of atoms, and P(x,y) is an atom; P(x,y) is the body of σ, denoted body(σ), while P(x,y) is the head of σ, denoted head(σ).

A negative constraint (NC) ν is a first-order formula of the form ∀x ϕ(x) → ¬y P(x,y), where x,y ∈ V, ϕ(x) is a conjunction of atoms, called the body of ν, denoted body(ν), and ϕ denotes the truth constant false; i.e., a contradiction. A Datalog² program is a finite set Σ of TGDs and NCs. For brevity, we often omit the universal quantifiers in front of TGDs and NCs, and write simply, e.g., ϕ(x) → ∃y P(x,y).

Moreover, we often speak simply of programs when referring to Datalog² programs.

Semantics. The semantics of programs is defined via homomorphisms. Briefly, a homomorphism is a substitution h : C U N U V → C U N U V that behaves as the identity over C. For a homomorphism h and a set of variables x, we denote by hₓ the restriction of h to x. The instance I satisfies the TGD σ, written I |= σ, if for every homomorphism h such that h(P(x,y)) ∈ I, there exists h’ ≥ hₓ such that h’(P(x,y)) ∈ I. The instance I satisfies the NC ν, written I |= ν, if there is no homomorphism h such that h(ϕ(x)) ∈ I. Given a program Σ, I satisfies Σ, written I |= Σ, if I satisfies each TGD and NC of Σ. I is a model of the program Σ relative to the database D, if D ⊆ I and I |= Σ. We denote the set of all models of Σ relative to D as mods(D,Σ).

Unions of Conjunctive Queries. A conjunctive query (CQ) is an existentially quantified formula ∃x ψ(x), where ψ is a conjunction of atoms. Consider, e.g., the query

q₁(x) = ∃y StarredIn(x,y) ∧ Mov(y),

which asks for individuals that starred in a movie. Notice that x is a free variable in q₁, also called an answer variable. A Boolean conjunctive query (BQ) is a CQ without any free variables. An example is the query

q₂ = ∃x, y StarredIn(x,y) ∧ Mov(y),

which asks whether there exists an individual that starred in a movie.

A union of Boolean conjunctive queries (UCQ) Q is a disjunction of BQs. For notational convenience, we write Q to represent UCQs and q to represent BQs. If we consider queries with free variables, we make this explicit and write Q(x), or q(x), respectively.

Query Semantics. The answers to a CQ q(x) over an instance I, denoted q(I), is the set of all mappings θ from x to the constants in I such that q(θ(x)) ∈ I. A Boolean query q has a positive answer over I, denoted I |= q, if q(I) ≠ ∅. Given a database D and a program Σ, the answers we consider are those that are true in all models of Σ relative to D. Formally, the answer to a CQ q w.r.t. D and Σ is the set of tuples ans(q, D, Σ) = {t | t ∈ q(I)}. The answer to a BQ q is positive, denoted D ∪ Σ |= q, if ans(q, D, Σ) ≠ ∅. These notions are generalized to the class of UCQs in the obvious way. Consider a database

D = {Actor(alPacino), StarredIn(pMiller, cw), Mov(cw)},

which asserts that Al Pacino is an actor, and that Penelope Miller has starred in a movie. The query q₁(x) produces only pMiller as an answer on D. In the presence of the program

Σ = {{Actor(x) → ∃y StarredIn(x,y), Mov(y)}},

a new tuple (alPacino) is generated, and thus both alPacino and pMiller become answers to q₁(x).

2.2 Computational Properties of Existential Rules

In general, it is undecidable whether a BQ has an answer or not w.r.t. a database D and a program Σ [4]. To regain decidability, many different restrictions on the class of allowed TGDs have been proposed. The most important (syntactic) restrictions studied in the literature are guardedness [8], stickiness [9], and acyclicity, along with their “weak” counterparts, namely weak guardedness [8], weak stickiness [9], and weak acyclicity [19], respectively.

A TGD σ is guarded, if there exists an atom a ∈ body(σ) that contains (or “guards”) all the body variables of σ. The class of guarded TGDs, denoted G, is defined as the family of all possible sets of guarded TGDs. A key subclass of guarded TGDs are the so-called linear TGDs with just one body atom, which is automatically the guard. The class of linear TGDs is denoted by L. Weakly guarded TGDs extend guarded TGDs by requiring only the body variables that are considered “harmful” to appear in the guard (see [8] for full details). The associated class of TGDs is denoted WG. It is easy to verify that L ⊆ G ⊆ WG, in terms of the sets of TGDs they contain.

Stickiness is inherently different from guardedness, and its central property can be described as follows: variables that appear more than once in a body (i.e., join variables) must always be propagated (or “stuck”) to the inferred atoms. A TGDs that enjoys this property is called sticky, and the class of sticky TGDs is denoted by S. Weak stickiness generalizes stickiness by considering only “harmful” variables, and defines the class WS of weakly sticky TGDs. Observe that S ⊆ WS.

A set Σ of TGDs is acyclic (and belongs to the class A), if its predicate graph is acyclic. Equivalently, an acyclic set of TGDs can be seen as a non-recursive set of TGDs. We say Σ is weakly-acyclic, if its dependency graph enjoys a certain acyclicity condition, which guarantees the existence of a finite canonical model; the associated class is denoted WA. Clearly, A ⊆ WA. Interestingly, it also holds that WA ⊆ WS [9].

Another key fragment of TGDs, which deserves our attention, are the so-called full TGDs, i.e., TGDs without existentially quantified

Notice that our definition of TGDs requires the head to contain only one atom. This restriction is made w.l.o.g., as a TGD with a conjunction of atoms in the head can be equivalently represented by a set of single-atom-headed TGDs [8].
variables. Their corresponding class is denoted as $F$. Restricting full TGDs to satisfy linearity, guardedness, stickiness, or acyclicity yields the classes $LF$, $GF$, $SF$, and $AF$, respectively. A known relation between these classes is that $F \subseteq WA$ [19] and $F \subseteq WG$ [8]. We extend all these notions to programs $\Sigma$ in the obvious way: by considering the properties satisfied by the TGDs in $\Sigma$. Thus, for instance, $\Sigma$ is guarded, if all the TGDs in $\Sigma$ are guarded.

When analysing the complexity of query answering, we consider all these classes of programs unless explicitly mentioned otherwise. To obtain a fine-grained analysis of the computational complexity, we follow Vardi’s taxonomy [40], as described next. The combined complexity of UCQ answering is considered by considering all the components, i.e., the database, the program, and the query, as part of the input. The bounded-arity combined complexity (or simply ba-combined complexity) assumes that the arity of the underlying schema (i.e., the maximum arity of the predicates in $R$) is bounded by an integer constant. In the context of description logics (DLs), the combined complexity in fact refers to the $ba$-combined complexity, since, by definition, the arity of the underlying schema is at most two. The fixed-program combined complexity (or simply fp-combined complexity) is calculated by considering the program (i.e., the set of TGDs and NCs) as fixed, while the data complexity additionally assumes that the query is fixed.

Table 1 summarizes the known complexity results for query entailment in the different classes of programs that we consider. These results will provide the basis for analysing the complexity of probabilistic Datalog$^\pm$ programs in the following sections.

We extend the special cases of Datalog$^\pm$ programs defined in the previous section to probabilistic programs in the obvious way. That is, the probabilistic program $\Gamma$ is guarded if the Datalog$^\pm$ program $\{ \lambda \mid (\lambda : \kappa) \in \Gamma \}$ is guarded, and analogously for linear, sticky, acyclic, and full programs, and their weak versions. For a class $\mathcal{L}$ of Datalog$^\pm$ programs, we denote by $\mathcal{T}_\mathcal{L}$ its associated class of probabilistic programs. Thus, for instance $\mathcal{T}_G$ is the class of all guarded probabilistic programs. Consider the probabilistic program $\Gamma_m$ relative to the PDB $P_m$ given in Figure 1. It asserts that actors star in at least one movie and that actors and movies are disjoint entities. Both expressions hold in the global context $\mathcal{T}$. To ease reading, we usually omit the global context from the expressions.

Intuitively, a probabilistic program relative to a PDB compactly encodes a finite number of classical programs relative a classical database, each of which associated with a different context, and therefore a number of worlds. This semantics is commonly referred to as the possible world semantics.

### Definition 2 (Possible Worlds)

Let $\mathcal{K} = (\Gamma, P)$ be a probabilistic knowledge base. Every world $w$ induces a classical knowledge base $\mathcal{K}_w = (\Gamma_w, P(w))$ where

$$\Gamma_w = \{ \lambda \mid (\lambda : \kappa) \in \Gamma, w \models \kappa \},$$

$$P(w) = \{ \ell \mid (\ell : \kappa) \in P, w \models \kappa \}.$$ 

A probabilistic knowledge base $\mathcal{K}$ is consistent, if all the worlds induced by $\mathcal{K}$ (with positive probability) are consistent.

The probabilistic program $\Gamma_m$ relative to $P_m$ encodes exponentially many worlds on the size of the context variables. For instance, given the world $w_1$ (see Figure 1), $P(w_1)$ contains all tuples from $\text{Actors}$ and $\text{Movies}$, but none from $\text{StarredIn}$. Similarly, as the rules in $\Gamma_m$ are global (i.e., they hold in every world), $\Gamma_{\{w_1\}}$ contains both rules. Observe also that tuple-independent probability models are a special case of our abstraction, where every annotation is independent from others. In this case, one can directly write probability values, instead of the contexts with their independent probabilities.

### Definition 3 (Query Semantics)

Let $\mathcal{K} = (\Gamma, P)$ be a probabilistic knowledge base, the probability of a UCQ $Q$ is given by:

$$P_K(Q) = \sum_{\kappa \models Q} P(w),$$

Given a query $Q$ and $p \in [0, 1]$, probabilistic query entailment is the problem of deciding whether $P_K(Q) \geq p$.

3 **Proabilistic Datalog$^\pm$**

To define our probabilistic extension of Datalog$^\pm$, we annotate all the rules and negative constraints with contexts, which will be interpreted through the probability distribution. Similarly, all the atoms in a probabilistic database are associated with a context as well.

### Definition 1 (Probabilistic Datalog$^\pm$)

A probabilistic TGD is an expression of the form $(\sigma : \kappa)$, where $\sigma$ is a TGD, and $\kappa$ is a context. Analogously, a probabilistic negative constraint is of the form $(\nu : \kappa)$, where $\nu$ is a negative constraint, and $\kappa$ is a context. A probabilistic program $\Gamma$ is a finite set of probabilistic TGDs and probabilistic negative constraints.

A probabilistic atom is of the form $(\ell : \kappa)$, where $\ell$ is an atom, and $\kappa$ is a context. A probabilistic database $P$ is a finite set of probabilistic atoms. A probabilistic knowledge base is a pair $\mathcal{K} = (\Gamma, P)$ that represents a probabilistic program $\Gamma$ relative to a probabilistic database $P$.

Our approach is based on annotating the facts in the database and the rules in the Datalog$^\pm$ program with Boolean events, which we call contexts. Here, we briefly introduce the basic notions, our assumptions, and the complexity of probabilistic Boolean inferences.

Consider a finite set of elementary events $E = \{ e_1, ..., e_n \}$. A world is a conjunction $w = s_1 \land ... \land s_m$ where $s_i \leq i \leq m$ is either the event $e_i$ or its negation $\neg e_i$. A context is a Boolean combination of elementary events, i.e., if $\kappa_1$ and $\kappa_2$ are contexts, then so is $\neg \kappa_1$, $\kappa_1 \land \kappa_2$.

Contexts encompass the probabilistic component of our formalism. For representing the probability distribution of events and contexts, we do not restrict to any specific probabilistic model, but rather consider any representation for which deciding whether $P(\kappa) > p$ for some value $p \in [0,1]$ is PP-complete. Further details on the complexity class PP and its relation to other complexity classes can be found in Section 3.1.
is \#P [39], which is a functional complexity class originally introduced in the context of counting problems. The corresponding decision class PP [20] defines the set of languages recognized by a polynomially bounded non-deterministic Turing machine (TM) that accepts an input if and only if more than half of the computation paths are accepting [38]; such machines are usually called PP TMs.

We also consider PP\(^{NP}\), resp., PP\(^{Σ^p_2}\), PP\(^{NP^p}\), which as usual corresponds to languages that can be recognized by a PP TM, with an NP (resp., Σ\(^p_2\), NEXP) oracle. Most of these classes belong to the counting polynomial-time hierarchy [41], which is partially illustrated in Figure 2: A portion of the counting polynomial-time hierarchy.

We consider the complexity of query answering w.r.t. the different classes of probabilistic programs relative to different languages.

\[ Γ_m \]

\[ R_1 : \langle \text{Actor}(x) \rightarrow \exists y \text{StarIn}(x, y), \text{Mov}(y) \rangle \]

\[ R_2 : \langle \text{Actor}(x), \text{Mov}(x) \rightarrow \bot \rangle \]

Figure 2 along with the first levels of the polynomial hierarchy. The following relations between complexity classes are a consequence of the relationships depicted in Figure 2 and will also be useful throughout the rest of this paper:

\[ \text{PP}^{NC} \subseteq \text{PSpace} \subseteq \text{EXP} \subseteq \text{NEXP} \subseteq \text{PP}^{NEXP} \subseteq 2\text{EXP} \]

### 3.2 Complexity Results

We start with a general result that provides some bounds for the complexity of query entailment in probabilistic KBs parameterized on the complexity of its classical counterpart.

**Theorem 4** Let \( L \) be a class of Datalog\(^+\) programs, and \( k \) be the complexity of query entailment in \( L \) relative to databases. Then, probabilistic query entailment in \( Σ_2^p \) relative to probabilistic databases is (i) \( k \)-hard, (ii) \( \text{PP}-hard \), and (iii) in \( \text{PP}^k \).

\(
\text{PP-hardness follows from the hardness of standard probabilistic inference. The full proof shows a construction of a probabilistic KB upon which standard query entailment can be decided, which proves \( k \)-hardness.}^5
\)

\(^5\) Membership to \( \text{PP}^k \) follows mainly from the observation that a probabilistic knowledge base is a factorized representation of exponentially many classical knowledge bases. Thus, it is possible to solve the problem (after properly adjusting the probabilities of the worlds) by deciding whether the majority of the oracle calls that decide classical query entailment return true.

We analyze the consequences of Theorem 4. Observe first that if \( k \) is a deterministic class that contains \( \text{PP} \), then \( \text{PP}^k = k \) and thus Theorem 4 directly provides tight complexity bounds. Notice that this is the case w.r.t. the combined complexities for all the classes except \( \text{A} \). In the case of the class \( \text{A} \), the complexity of query entailment

\[^5\] For ease of presentation, we excluded the proofs from the main text; for the interested reader, we refer to the appendix of this paper.
is complete w.r.t. to the class NEXP, and it is not known whether PP^{NEXP} ⊆ NEXP. We observe that the non-determinism in the oracle NEXP calls are used in a restricted fashion; this allows us to encode the problem into exponentially many NEXP TMs, which can be simulated with a NEXP TM.

**Lemma 5** Probabilistic query entailment in ΥA relative to a probabilistic database is in NEXP w.r.t. the combined complexity.

With the help of Lemma 5 and Theorem 4, we conclude that for all the rule languages, the complexity of probabilistic entailment remains the same w.r.t. the combined complexity (see the second column in Table 2). Clearly, this result transfers to the case where all events are assumed to be independent. Notice, however, that the implication of Theorem 4 is stronger, as it also yields tight complexity bounds for the languages G, WG, WS, and WA w.r.t. ba-combined complexity, as well as for the language WG w.r.t. fp-combined complexity. For the remaining languages, where k = NP, we prove Theorem 6.

**Theorem 6** If query entailment in L relative to databases w.r.t. ba-combined (resp., fp-combined) complexity is NP-complete, then probabilistic query entailment in ΥL relative to probabilistic databases is PP^{NP}-complete w.r.t. ba-combined (resp., fp-combined) complexity.

Membership in PP^{NP} is shown by a setting appropriate threshold values and iterating over nondeterministic oracle calls until this threshold value is exceeded. To show hardness for this class, we require more involved technical constructions. For these constructions, we use the M-\exists QBF problem [41].

**Definition 7 (M-\exists QBF)** Given an integer constant c and a partially quantified Boolean formula of the form

\[
\Phi = \exists y_1 \ldots y_m \phi_1 \land \phi_2 \land \cdots \land \phi_k,
\]

where every \(\phi_i\) is a clause over \{x_1, \ldots, x_l; y_1, \ldots, y_m\} and \(k, l, m \geq 1\); M-\exists QBF (Φ, c) is to decide whether for at least c of the truth assignments \(\tau\) to \(x_1, \ldots, x_l\), the formula \(\tau(\Phi)\) is true.

Note that M-\exists QBF is different from majority satisfiability, as here the threshold is set by an integer (not necessarily majority). M-\exists QBF is an PP^{NP}-complete problem even if the clauses \(\phi_i\) are restricted to \(3CNF\) [3].

The full proof constructs a probabilistic knowledge base \(K_0 = (\emptyset, P_0)\) and a special query \(Q_0\) based on \(\Phi, K_0\) and \(Q_0\) together simulate the satisfiability conditions for the formula \(\Phi\). Moreover, the atoms in \(P_0\) are associated with partial assignments over the variables \{x_1 \ldots x_l\}. Notice that these are precisely the variables upon which we want to decide whether the number of assignments are at least c. This construction allows us to factorize the satisfiability problem over the variables \{x_1 \ldots x_l\} and thus to obtain the result. As \(K_0\) uses an empty program, and all atoms are bounded in the arity by 3, we obtain tight complexity bounds for all entries in Table 2.

We have analyzed the complexity of probabilistic query entailment under the standard possible world semantics. Using novel constructions, we have provided tight complexity bounds for all languages under consideration. Table 2 shows our results. Next, we provide concrete examples on how the possible world semantics can be incompetent under certain conditions, and concentrate on a different semantics.

4 **INCONSISTENCY HANDLING**

Due to the presence of negative constraints, knowledge bases may contain contradictory knowledge. In fact, this has lead to a quest of finding alternative semantics to be able deal with inconsistent knowledge in ontologies. Consider for example the knowledge base

\[
\Sigma_{inc} = \{P(x), B(x) \rightarrow \bot\} \quad \text{and} \quad D_{inc} = \{P(u), B(u), P(v)\}.
\]

The NC requires the predicates \(P\) and \(R\) to be disjoint, but the database states that \(u\) belongs to both of them. Thus, the program has no model relative to the database. The fact that a knowledge base contains an inconsistency makes standard reasoning very problematic, as anything can be entailed from an inconsistent knowledge base ("ex falso quodlibet") under the standard semantics. Consequently, one loses the ability of distinguishing between queries. From a technical perspective, the inconsistency problem immediately propagates to probabilistic extensions. Consider a probabilistic variant of our example; i.e., the KB \(K_{inc} = (\Gamma_{inc}, P_{inc})\), where

\[
\Gamma_{inc} = \{(P(x), R(x) \rightarrow \bot)\} \quad \text{and} \quad P_{inc} = \{(P(u) : s_1), (B(u) : s_2), (P(v) : s_1 \land s_2)\},
\]

and \(P(s_1), P(s_2), P(s_1 \land s_2) > 0\). Observe that \(K_{inc}\) factorizes into worlds with positive probability that contain inconsistent knowledge. More concretely, it imposes 4 worlds, one of which is inconsistent, i.e., the one that contains both \((P(u))\) and \((B(u))\). Notice that, even though a vast majority of the worlds are consistent, the knowledge base as a whole is inconsistent, as it assigns a positive probability to an inconsistent world. It is possible to slightly change the possible world semantics to only consider consistent worlds by setting the probabilities of inconsistent worlds to 0 and renormalizing the probability distribution over the set of worlds accordingly. More precisely, assuming \(\sum_{w \models \bot} P_K(w) < 1\), we obtain the distribution:

\[
P(w) = \begin{cases} 0 & \text{if } w \models \bot \\ P_K(w)/(1 - \sum_{w \models \bot} P_K(w')) & \text{otherwise} \end{cases}
\]

Notice that this semantics assumes that the error is in the probability distribution; accordingly, it modifies the distribution. For our example, this yields a 0 probability for \(P(v)\). Moreover, in the same example, \(P(u)\) and \(R(u)\) evaluate to a positive probability value w.r.t. this semantics. This is not in line with the intuition; particularly, because it puts more responsibility on \(P(v)\) than it puts on the other tuples although \(P(v)\) does not contribute to the inconsistency. On the other hand, assuming that the error is on the logical side, it is easy to see that responsibility needs to be shared only by the NC \(\{P(x), R(x) \rightarrow \bot\}\) and the tuples \(\{P(u), R(u)\}\), since they serve as the source of inconsistency. Thus, it is more intuitive to expect the probability of \(P(v)\) to remain the same, as it does not contribute to inconsistency in the logical sense.

The main question is then, how to identify the meaningful answers in inconsistent worlds. We base ourselves on the recent advances on inconsistency-tolerant reasoning developed for Datalog^{\exists} [28, 29, 27] and provide an inconsistency-tolerant possible world semantics. We also show that under this semantics, the probability of \(P(v)\) remains the same.

Several inconsistency-tolerant semantics have been proposed in the literature. One of the central semantics is first developed for relational databases [1] and then generalized as the AR semantics for several DLs [26]. The AR semantics is based on the key notion of a repair, which is a \(\subseteq\)-maximal consistent subset of the given
easy to verify that is to decide whether $\mathcal{K}$. The query semantics then consid-
erate these are all possible repairs. The query semantics then consid-
products, denoted GR-UCQ. For further details, we refer to [18].

We now extend the generalized repair (GR) semantics to probabilis-

Definition 8 (Flexible programs and databases) A flexible PDB is a pair $P = (P_h; P_s)$ of two PDBs $P_h$ and $P_s$, denoted hard and soft PDB, respectively, while a flexible (probabilistic) program is a pair $\Gamma = (\Gamma_h; \Gamma_s)$ consisting of a finite set $\Gamma_h$ of TGDs and NCs and a finite set $\Gamma_s$ of TGDs, denoted hard and soft program, respectively.

Consider again the probabilistic KB $\mathcal{K}_{inc} = (\Gamma_{inc}, P_{inc})$, where we would like to fix the whole program, and let the whole database be a soft PDB. This can be achieved by setting $\Gamma_{inc} = (\Gamma_h, \emptyset)$ and $P_{inc} = (\emptyset, P_s)$, where $\Gamma_h = \Gamma_{inc}$ and $P_{inc} = P_s$. This partition fixes the program and views the whole PDB as a soft database. The notion of generalized repair (GR) for flexible PDBs under flexible probabilistic programs is then given as follows.

Definition 9 (Generalized repair) A generalized repair of a flexible PDB $(P_h; P_s)$ and a flexible program $(\Gamma_h; \Gamma_s)$ is a probabilistic KB $\mathcal{K} = ((\Gamma_h; \Gamma_s); (P_h; P_s))$, where $\Gamma_s \subseteq \Gamma_s$ and $P_s \subseteq P$ such that (i) $\Gamma_h \cup \Gamma_s \cup P_h \cup P_s$ is consistent, and (ii) there is no $t \in (\Gamma_h \cup P_h \cup \Gamma_s \cup P_s)$ such that $(\Gamma_h \cup \Gamma_s \cup P_h \cup P_s \cup \{t\})$ is consistent. The set of all such repairs is denoted by $rep(\mathcal{K})$.

Clearly, there may be many $c$-maximal repairs for every world: Observe that $K_{inc} = \Sigma_{inc} \cup D_{inc}$ is a world over $K_{inc}$. Here, both $K_{inc}/\{P(u)\}$ and $K_{inc}/\{R(u)\}$ are $c$-maximal repairs. In this case, all are possible repairs. The query semantics then considers the consequences that are entailed from every $c$-maximal repair, i.e., the safe consequences.

Definition 10 (Inconsistency tolerant query semantics) Let $\mathcal{K}$ be a probabilistic KB, the probability of a UCQ $Q$ is given by:

$$P_{\mathcal{K}}(Q) = \sum_{\mathcal{K}_{inc} \models_{GR} Q} P(w),$$

where $\mathcal{K}_{inc} \models_{GR} Q$ holds iff for all repairs $r \in rep(\mathcal{K}_{inc})$, it holds that $r \models Q$. Given a query $Q$ and $p \in (0, 1)$, probabilistic GR-UCQ entailment is to decide whether $P_{\mathcal{K}}(Q) \geq p$.

The implication of this semantics is clear. Consider again $K_{inc}$: It is easy to verify that $P(v)$ is entailed from all repairs for the inconsistent worlds. Therefore, it yields the same probability for $P(v)$, as desired.

Table 3: Complexity of GR-BQ entailment under existential rules [18]; all entries are completeness results. Hardness holds even in the case where the whole database is soft, and the whole program is hard.

Table 4: Complexity of probabilistic GR-UCQ entailment under existential rules; all entries but the “in” ones are completeness results. Hardness holds even in the case where the whole database is soft and the whole program is hard.

4.1 Complexity Results

As before, we will consider the complexity of query answering w.r.t. the different classes of probabilistic programs relative to different languages. Observe first that Theorem 4 is rather general, and thus, all the results can be transferred to this semantics.

Corollary 11 Let $k$ be the complexity of GR-UCQ entailment in $L$ relative to a databases; then probabilistic GR-UCQ entailment in $\mathcal{L}$ relative to probabilistic databases is $k$-hard, PP-hard, and in $\text{PP}^\text{NEXP}$.

As before, this yields tight complexity bounds for languages where $k$ is a deterministic class that contains PP. The language $A_L$ requires a special attention, as the complexity of GR-UCQ entailment in $A_L$ is $\text{P}^{\text{NEXP}}$-complete. We provide an upper bound for probabilistic GR-UCQ entailment.

Lemma 12 Probabilistic GR-UCQ entailment in $\mathcal{L}$ relative to probabilistic databases is in $\text{PP}^{\text{NEXP}}$ w.r.t. the combined and ba-combined complexity.

Although we expect this problem to be complete for the class $\text{PP}^{\text{NEXP}}$, it is yet open whether this problem is $\text{PP}^{\text{NEXP}}$-hard. The results for ba-combined and fa-combined cases require a much more detailed analysis. We prove the following Theorem.

Theorem 13 Let $k = \Pi^p_2$ be the complexity of GR-UCQ entailment in the rule language $\mathcal{L}$ relative to databases w.r.t. combined (resp., fp-combined) complexity. Then, probabilistic GR-UCQ entailment in $\mathcal{L}$ relative to a probabilistic databases is complete in the class $\text{PP}^{\text{NEXP}}$ w.r.t. ba-combined (resp., fp-combined) complexity.

While upper bounds can be shown using analogous arguments as in the standard semantics, to be able to show hardness, we first define a problem that is complete for the class $\text{PP}^{\text{NEXP}}$, adopted from [41].

Definition 14 (M-\(\forall\exists\)QBF) Given a integer constant $c$ and a partially quantified Boolean formula of the form

$$\Phi = \forall y_1 \ldots y_m \exists z_1 \ldots z_n \phi_1 \land \phi_2 \land \cdots \land \phi_k,$$

where every $\phi_i$ is a clause over $\{x_1, \ldots, x_l, y_1, \ldots, y_m, z_1, \ldots, z_n\}$ and $k, l, m, n \geq 1$, $\text{M-}\forall\exists\text{QBF}(\Phi, c)$ is to decide whether for at least $c$ of the truth assignments $\tau$ to $x_1, \ldots, x_l$, the formula $\tau(\Phi)$ is true.

For an arbitrary instance of M-\(\forall\exists\)QBF, where the clauses are restricted to 3CNF, we construct a probabilistic knowledge base that consists of a program that contains a single negative constraint. The reduction is correct and of polynomial size. As the KB provided is
in the intersection of the class of languages considered, we obtain
hardness for all of these languages.

Our last result is about data complexities, for which GR-UCQ en-
tailment is coNP-complete (except for the class $\mathcal{W}_G$, which has
exponential data complexity). We prove the following Theorem.

**Theorem 15** If GR-UCQ entailment in $\mathcal{L}$ relative to databases is
coNP-complete (or NP-complete) in data complexity, then the data
complexity of probabilistic GR-UCQ entailment in $\Upsilon_\mathcal{L}$ relative to
probabilistic databases is $\text{PP}^\text{PP}$-complete.

We use the canonical problem $\text{M-\exists QBF}$ to show hardness. Ob-
serve, however, that this requires a very different construction than
the one in Theorem 6, as here the query is fixed. This result con-
cludes our complexity analysis for inconsistency-tolerant semantics; all
of the results are summarized in Table 4.

# 5 RELATED WORK

Our work is closely related to probabilistic databases [37, 12]. In fact,
probabilistic Datalog can be seen as a generalization of PDBs. As in
PDBs, query answering in probabilistic Datalog is PP-hard. Notice
the novel dichotomy result in tuple-independent PDBs that classifies
the unions of conjunctive queries as either being safe (P), or unsafe
(#{P-hard}) [13]. Identifying special cases (as in [24]) of probabilistic
Datalog that allows similar dichotomies is part of the future work.

We also note the recent work on Open-World PDBs [10], which al-
lows a more flexible representation for PDBs by providing default
probability intervals for unknown facts; significantly, this extended
setting preserves the full dichotomy result for UCQs.

The possible world semantics is widely employed in probabilis-
tic logic programming [34, 25, 35], and probabilistic query answer-
ing has been studied in light-weight probabilistic ontology languages
[11, 14, 24] before; see especially [30] for an overview of probabilis-
tic ontology languages. Our approach differs in several aspects: First,
we consider a family of existential rule languages that is known to be
well-behaved and provide tight complexity bounds for reasoning in
these languages for all of the cases except one. Second, our assump-
tions are rather flexible, as we do not require a specific probabilistic
model. Lastly, we propose an inconsistency-tolerant semantics, based
on [18], and study query evaluation under this semantics. Notice that
inconsistency-tolerant semantics have been studied in Datalog [21]
before, which we find closely related. Differently, we adopt a more
general repair semantics, as we allow repairs both on the data and on
the program, and it is possible to partition the knowledge base into
hard and soft components. Finally, we consider the full Datalog family
(not only guarded rules), providing a complete picture of the
complexity of query evaluation.

# 6 SUMMARY AND OUTLOOK

We have studied probabilistic query entailment in Datalog under
the standard possible world semantics and under an inconsistency-
tolerant variant of it. We have shown that the inconsistency-tolerant
semantics provides more information, while pushing the computa-
tional complexity of probabilistic query entailment higher in the
counting polynomial-time hierarchy in many cases. The differences
between these two semantic considerations represent yet another
trade-off between retrieving more information on the one side and
the increasing computational cost on the other side. Our analysis is
purely complexity-theoretical, and it is an open research problem to
find special cases where efficient algorithms can be developed. Such
algorithms can take the advantage of existing methods in knowl-
edge compilation [15, 7], as performing operations on a pre-compiled
structure is known to be very efficient.

# A PROOF SKETCH FOR THEOREM 4

We prove the result only w.r.t. the data complexity; the result w.r.t.
the so-called, $\text{fa}$-combined, and combined complexity can be ob-
tained using analogous arguments.

(Hardness) Let $k$ be the data complexity of query entailment in $\mathcal{L}$.
Probabilistic query entailment w.r.t. the data complexity is PP-hard,
as it is already so in PDBs w.r.t. data complexity. Thus, we only
need to show that $\mathcal{L}$-hardness w.r.t. data complexity. Suppose that prob-
abilistic query entailment is not $\mathcal{L}$-hard in $\Upsilon_\mathcal{L}$ w.r.t. the data
complexity. Let $\Sigma$ be an arbitrary program relative to an arbitrary
database $D = \{l_i \mid 1 \leq i \leq n\}$ and construct the probabilistic KB $\mathcal{K}' = \langle \Gamma', P' \rangle$ where

$$\Gamma' = \{\lambda \mid \lambda \in \Sigma\}, \ P' = \{\{l_i : 0.5\} \mid l_i \in D, 1 \leq i \leq n\}.$$  

Clearly, this construction is polynomial, and given a query $Q'$, it is
easy to see that

$$(\Sigma, D) \models Q' \text{ holds iff } P(Q') > 0.5^n,$$

which implies that query answering in $\mathcal{L}$ is not $\mathcal{L}$-hard in the data
complexity, which leads to a contradiction.

(Membership) We assume that the probability of each world is com-
putable in polynomial time, that is it is a rational number, and that the
rational numbers of the probabilities of all worlds have the same
denominator. As for membership in $\text{PP}$, intuitively, we first create mul-
tiples of each world (which then correspond to the nondeterministic
branches of a Turing machine), so that the probability distribution
over all thus generated worlds is the uniform distribution. Then, for
thresholds properly below (resp., above) 0.5, we introduce artificial
success (resp., failure) worlds (which correspond to other nondeter-
ministic success (resp., failure) branches of a Turing machine), so
that satisfying the resulting threshold corresponds to having a major-
ity of success worlds. We thus only have to verify whether for the
majority of the worlds, the query evaluates to true. As query evalua-
tion is in $k$, the computation is overall in $\text{PP}^k$. □

# B PROOF SKETCH FOR LEMMA 5

Let $Q$ be a UCQ, and $\mathcal{K} = \langle \Gamma, P \rangle$ be an arbitrary probabilistic
knowledge base where $\Gamma$ is defined over $\Upsilon_A$. By Definition 3, it suf-
fices to decide whether \( \sum_{\mathcal{K}, w_i \models Q} P(w) \geq p \). Let $W$ be the set of all
worlds $w$. Guess a subset \( \{w_1, \ldots, w_n\} \subseteq W \) and verify whether

$$(1) \sum_{\mathcal{K}, w_i \models Q} P(w_i) \geq p \text{ for all } \{w_i \mid 1 \leq i \leq n\} \text{ and } (2) \sum_{i=1}^{n} P(w_i) \geq p.$$  

It is easy to see that this procedure yields the correct decision.

We only need to show that this procedure is in $\text{NEXP}$. First, observe
that the guess is of size exponential and can be produced by a non-deterministic Turing machine that runs in exponential time. Second, the verification of (1) can be done in \( (\text{EXP} \times \text{NEXP}) = \text{NEXP} \), as there are exponentially many worlds and \( k = \text{NEXP} \). Finally, the verification of (2) can be done by traversing over exponentially many worlds and computing their probabilities. As the latter can be done in polynomial time, this verification is clearly in \( \text{EXP} \).

\[\square\]

C PROOF SKETCH FOR THEOREM 6

(Membership) This result is a consequence of Theorem 4, where \( k \) is set to \( \text{NP} \).

(Hardness) To show hardness, we provide a reduction from the \( M-\text{3QBF} \) problem (Definition 7). Let the formula in 3CNF

\[\Phi = \exists y_1 \ldots y_m \phi_1 \land \phi_2 \land \ldots \land \phi_k,\]

be a partially quantified Boolean formula defined over \( V = \{x_1, \ldots, x_l, y_1, \ldots, y_m\} \), where every \( \phi_i \) is a disjunction of three literals, and \( c \) is an integer constant. For every clause \( \phi_i = \exists u_i \lor \exists v_i \lor \exists w_i \), define ground atoms \( M_i(\nu_i(u_i), \nu_i(v_i), \nu_i(w_i)) \), where \( \nu_i \) is a truth assignment to the variables \( u_i, v_i, w_i \) that satisfies \( \phi_i \). Observe that, for every clause, the number of such assignments is bounded by \( 2^3 \). The partial assignment \( \nu_{s_1 \ldots s_n} \) denotes the restriction of \( \nu \) to the variables \( \{s_1, \ldots, s_n\} \). We construct the probabilistic KB \( K_{\Phi} = (\Gamma_{\Phi}, \mathcal{P}_{\Phi}) \), where

\[\mathcal{P}_{\Phi} = \{ \{ M_i(\nu_i(u_i), \nu_i(v_i), \nu_i(w_i)) : \nu_i(\{x_1, \ldots, x_l\} \cap \{u_i, v_i, w_i\}) \} \mid \nu_i(\phi_i) \models \phi_i, 1 \leq i \leq k \}.\]

Let the event space be defined over the \( x \)-variables such that every world has the probability \( 0.5^l \). For the query

\[Q_{\Phi} = \exists x_1 \ldots x_l, y_1 \ldots y_m \bigwedge_{i=1}^k M_i(u_i, v_i, w_i),\]

we obtain the following reduction:

\[P_{K_{\Phi}}(Q) \geq c \cdot 0.5^l \text{ iff } M-\text{3QBF}(\Phi, c) \text{ answers yes.}\]

Observe that the above reduction can clearly be done in polynomial time in the size of \( \Phi \), that the resulting probabilistic program is fixed and consists only of one NC, and the arity of all predicates is at most 3.

\[\square\]

D PROOF SKETCH FOR THEOREM 13

(Membership) This result is a consequence of Theorem 4 and Corollary 11, where \( k \) is set to \( \text{coNP} \), and the fact that \( \text{PP}^{\text{coNP}} = \text{PP}^{\text{NP}} \).

(Hardness) We provide a reduction from the \( \text{P}^{\text{NP}} \)-complete problem of, given a partially quantified Boolean formula

\[\Phi = \forall y_1 \ldots y_m \phi_1 \lor \phi_2 \lor \ldots \lor \phi_k,\]

over \( V = \{x_1, \ldots, x_l, y_1, \ldots, y_m\} \), where every \( \phi_i \) is a conjunction of three literals, and an integer constant \( c \), deciding whether for at least \( c \) truth assignments \( \tau \) to \( x_1 \ldots x_l \), the formula

\[\forall y_1 \ldots y_m \bigwedge_{i=1}^k M_i(u_i, v_i, w_i) \land \bigwedge_{i=1}^m S(y_i, y'_i),\]

we obtain that \( P_{K_{\Phi}}(Q) \geq c \cdot 0.5^l \text{ iff } \text{P}^{\text{NP}}(\phi, c) \text{ answers yes.}\)

Observe that the above reduction can clearly be done in polynomial time in the size of \( \Phi \), that the resulting probabilistic program is fixed and consists only of one NC, and the arity of all predicates is at most 3.

\[\square\]

E PROOF SKETCH FOR THEOREM 15

(Membership) This result is a consequence of Theorem 4 and Corollary 11, where \( k \) is set to \( \text{NP} \), and the fact that \( \text{P}^{\text{NP}} = \text{P}^{\text{NP}} \).

(Hardness) We provide a reduction from the \( \text{P}^{\text{NP}} \)-complete problem of, given a partially quantified Boolean formula

\[\Phi = \forall y_1 \ldots y_m \phi_1 \lor \phi_2 \lor \ldots \lor \phi_k,\]

over \( V = \{x_1, \ldots, x_l, y_1, \ldots, y_m\} \), where every \( \phi_i \) is a conjunction of three literals, and an integer constant \( c \), deciding whether for at least \( c \) truth assignments \( \tau \) to \( x_1 \ldots x_l \), the formula

\[\forall y_1 \ldots y_m \bigwedge_{i=1}^k M_i(u_i, v_i, w_i) \land \bigwedge_{i=1}^m S(y_i, y'_i),\]

we obtain the following reduction:

\[P_{K_{\Phi}}(Q) \geq c \cdot 0.5^l \text{ iff } \text{P}^{\text{NP}}(\phi, c) \text{ answers yes.}\]

Observe that the above reduction can clearly be done in polynomial time in the size of \( \Phi \), that the resulting probabilistic program is fixed and consists only of one NC, and the arity of all predicates is at most 3.
