

DATABASE THEORY

Lecture 4: Complexity of FO Query Answering

Markus Krötzsch

Knowledge-Based Systems

TU Dresden, 17th Apr 2018

How to Measure Query Answering Complexity

Query answering as decision problem

→ consider Boolean queries

Various notions of complexity:

- Combined complexity (complexity w.r.t. size of query and database instance)
- Data complexity (worst case complexity for any fixed query)
- Query complexity (worst case complexity for any fixed database instance)

Various common complexity classes:

$$L \subseteq NL \subseteq P \subseteq NP \subseteq PSpace \subseteq ExpTime$$

An Algorithm for Evaluating FO Queries

function Eval(φ, I)

```
01  switch ( $\varphi$ ) {  
02      case  $p(c_1, \dots, c_n)$  : return  $\langle c_1, \dots, c_n \rangle \in p^I$   
03      case  $\neg\psi$  : return  $\neg$ Eval( $\psi, I$ )  
04      case  $\psi_1 \wedge \psi_2$  : return Eval( $\psi_1, I$ )  $\wedge$  Eval( $\psi_2, I$ )  
05      case  $\exists x.\psi$  :  
06          for  $c \in \Delta^I$  {  
07              if Eval( $\psi[x \mapsto c], I$ ) then return true  
08          }  
09      return false  
10 }
```

FO Algorithm Worst-Case Runtime

Let m be the size of φ , and let $n = |\mathcal{I}|$ (total table sizes)

FO Algorithm Worst-Case Runtime

Let m be the size of φ , and let $n = |\mathcal{I}|$ (total table sizes)

- How many recursive calls of Eval are there?
 \leadsto one per subexpression: at most m
- Maximum depth of recursion?
 \leadsto bounded by total number of calls: at most m
- Maximum number of iterations of **for** loop?
 $\leadsto |\Delta^{\mathcal{I}}| \leq n$ per recursion level
 \leadsto at most n^m iterations
- Checking $\langle c_1, \dots, c_n \rangle \in p^{\mathcal{I}}$ can be done in linear time w.r.t. n

Runtime in $m \cdot n^m \cdot n = m \cdot n^{m+1}$

Time Complexity of FO Algorithm

Let m be the size of φ , and let $n = |\mathcal{I}|$ (total table sizes)

Runtime in $m \cdot n^{m+1}$

Time complexity of FO query evaluation

- Combined complexity: in ExpTime
- Data complexity (m is constant): in P
- Query complexity (n is constant): in ExpTime

FO Algorithm Worst-Case Memory Usage

We can get better complexity bounds by looking at memory

Let m be the size of φ , and let $n = |\mathcal{I}|$ (total table sizes)

- For each (recursive) call, store pointer to current subexpression of φ : $\log m$
- For each variable in φ (at most m), store current constant assignment (as a pointer): $m \cdot \log n$
- Checking $\langle c_1, \dots, c_n \rangle \in p^{\mathcal{I}}$ can be done in logarithmic space w.r.t. n

Memory in $m \log m + m \log n + \log n = m \log m + (m + 1) \log n$

Space Complexity of FO Algorithm

Let m be the size of φ , and let $n = |\mathcal{I}|$ (total table sizes)

Memory in $m \log m + (m + 1) \log n$

Space complexity of FO query evaluation

- Combined complexity: in PSpace
- Data complexity (m is constant): in L
- Query complexity (n is constant): in PSpace

FO Combined Complexity

The algorithm shows that FO query evaluation is in PSpace.

Is this the best we can get?

Hardness proof: reduce a known PSpace-hard problem to FO query evaluation

FO Combined Complexity

The algorithm shows that FO query evaluation is in PSpace.

Is this the best we can get?

Hardness proof: reduce a known PSpace-hard problem to FO query evaluation
 \leadsto QBF satisfiability

Let $\mathcal{Q}_1 X_1. \mathcal{Q}_2 X_2. \dots \mathcal{Q}_n X_n. \varphi[X_1, \dots, X_n]$ be a QBF (with $\mathcal{Q}_i \in \{\forall, \exists\}$)

- Database instance \mathcal{I} with $\Delta^{\mathcal{I}} = \{0, 1\}$
- One table with one row: true(1)
- Transform input QBF into Boolean FO query

$$\mathcal{Q}_1 x_1. \mathcal{Q}_2 x_2. \dots \mathcal{Q}_n x_n. \varphi[X_1 \mapsto \text{true}(x_1), \dots, X_n \mapsto \text{true}(x_n)]$$

It is easy to check that this yields the required reduction. □

PSpace-hardness for DI Queries

The previous reduction from QBF may lead to a query that is not domain independent

Example: QBF $\exists p. \neg p$ leads to FO query $\exists x. \neg \text{true}(x)$

PSpace-hardness for DI Queries

The previous reduction from QBF may lead to a query that is not domain independent

Example: QBF $\exists p. \neg p$ leads to FO query $\exists x. \neg \text{true}(x)$

Better approach:

- Consider QBF $\mathcal{Q}_1 X_1. \mathcal{Q}_2 X_2. \dots \mathcal{Q}_n X_n. \varphi[X_1, \dots, X_n]$ with φ in negation normal form: negations only occur directly before variables X_i (still PSpace-complete: exercise)
- Database instance \mathcal{I} with $\Delta^{\mathcal{I}} = \{0, 1\}$
- Two tables with one row each: true(1) and false(0)
- Transform input QBF into Boolean FO query

$$\mathcal{Q}_1 x_1. \mathcal{Q}_2 x_2. \dots \mathcal{Q}_n x_n. \varphi'$$

where φ' is obtained by replacing each negated variable $\neg X_i$ with false(x_i) and each non-negated variable X_i with true(x_i).

Combined Complexity of FO Query Answering

Summing up, we obtain:

Theorem 4.1: The evaluation of FO queries is PSpace-complete with respect to combined complexity.

Combined Complexity of FO Query Answering

Summing up, we obtain:

Theorem 4.1: The evaluation of FO queries is PSpace-complete with respect to combined complexity.

We have actually shown something stronger:

Theorem 4.2: The evaluation of FO queries is PSpace-complete with respect to query complexity.

Summary and Outlook

The evaluation of FO queries is

- PSpace-complete for combined complexity
- PSpace-complete for query complexity

Open questions:

- What is the data complexity of FO queries?
- Are there query languages with lower complexities? (next lecture)
- Which other computing problems are interesting?
