What is a Query?

The relational queries considered so far produced a result table from a database. We generalize slightly.

**Definition**

- Syntax: a query expression \( q \) is a word from a query language (algebra expression, logical expression, etc.)
- Semantics: a query mapping \( M[q] \) is a function that maps a database instance \( I \) to a database instance \( M[q](I) \)

\( \Rightarrow \) a “result table” is a result database instance with one table.

\( \Rightarrow \) for some semantics, query mappings are not defined on all database instances

Generic Queries

We only consider queries that do not depend on the concrete names given to constants in the database:

**Definition**

A query \( q \) is **generic** if, for every bijective renaming function \( \mu : \text{dom} \rightarrow \text{dom} \) and database instance \( I \):

\[
\mu(M[q](I)) = M[\mu(q)](\mu(I)).
\]

In this case, \( M[q] \) is **closed under isomorphisms**.
First-order Logic as a Query Language

Idea: database instances are finite first-order interpretations
⇝ use first-order formulae as query language
⇝ use unnamed perspective (more natural here)

Examples (using schema as in previous lecture):
• Find all bus lines: \( \text{Lines}(x, \text{"bus"}) \)
• Find all possible types of lines: \( \exists y. \text{Lines}(y, x) \)
• Find all lines that depart from an accessible stop:
  \[ \exists y. \text{Stops}(y, \text{Stop}, \text{"true"}) \land \text{Connect}(y, \text{To}, x) \]

First-order Logic with Equality: Syntax

Basic building blocks:
• Predicate names with an arity \( \geq 0 \): \( p, q, \text{Lines}, \text{Stops} \)
• Variables: \( x, y, z \)
• Constants: \( a, b, c \)
• Terms are variables or constants: \( s, t \)

Formulae of first-order logic are defined as usual:
\[
\varphi ::= p(t_1, \ldots, t_n) \mid t_1 \approx t_2 \mid \neg \varphi \mid \varphi \land \varphi \mid \varphi \lor \varphi \mid \exists x. \varphi \mid \forall x. \varphi
\]

where \( p \) is an \( n \)-ary predicate, \( t_i \) are terms, and \( x \) is a variable.
• An atom is a formula of the form \( p(t_1, \ldots, t_n) \)
• A literal is an atom or a negated atom
• Occurrences of variables in the scope of a quantifier are bound; other occurrences of variables are free

First-order Logic Syntax: Simplifications

We use the usual shortcuts and simplifications:
• flat conjunctions \( (\varphi_1 \land \varphi_2 \land \varphi_3) \) instead of \( (\varphi_1 \land (\varphi_2 \land \varphi_3)) \)
• flat disjunctions (similar)
• flat quantifiers \( (\exists x, y, z. \varphi) \) instead of \( \exists x. \exists y. \exists z. \varphi \)
• \( \varphi \rightarrow \psi \) as shortcut for \( \neg \varphi \lor \psi \)
• \( \varphi \leftrightarrow \psi \) as shortcut for \( (\varphi \rightarrow \psi) \land (\psi \rightarrow \varphi) \)
• \( t_1 \neq t_2 \) as shortcut for \( \neg (t_1 \approx t_2) \)

But we always use parentheses to clarify nesting of \( \land \) and \( \lor \):
No “\( \varphi_1 \land \varphi_2 \lor \varphi_3 \)"!
First-order Logic with Equality: Semantics

First-order formulae are evaluated over interpretations \( \langle \Delta^I, I \rangle \), where \( \Delta^I \) is the domain. To interpret formulas with free variables, we need a variable assignment \( Z : \text{Var} \rightarrow \Delta^I \).

- constants \( a \) interpreted as \( a^I, Z = a^I \in \Delta^I \)
- variables \( x \) interpreted as \( x^I, Z = Z(x) \in \Delta^I \)
- \( n \)-ary predicates \( p \) interpreted as \( p^I \subseteq (\Delta^I)^n \)

A formula \( \varphi \) can be satisfied by \( I \) and \( Z \), written \( I, Z \models \varphi \):

- \( I, Z \models p(t_1, \ldots, t_n) \) if \( \{ t_1^I, \ldots, t_n^I, Z \} \in p^I \)
- \( I, Z \models t_1 \approx t_2 \) if \( t_1^I = t_2^I \)
- \( I, Z \models \neg \varphi \) if \( I, Z \not\models \varphi \)
- \( I, Z \models \varphi \land \psi \) if \( I, Z \models \varphi \) and \( I, Z \models \psi \)
- \( I, Z \models \varphi \lor \psi \) if \( I, Z \models \varphi \) or \( I, Z \models \psi \)
- \( I, Z \models \exists x. \varphi \) if there is \( \delta \in \Delta^I \) with \( I, \{ x \mapsto \delta \}, Z \models \varphi \)
- \( I, Z \models \forall x. \varphi \) if for all \( \delta \in \Delta^I \) we have \( I, \{ x \mapsto \delta \}, Z \models \varphi \)

Boolean Queries

A **Boolean query** is a query of arity 0

\[ \neg \text{Lines}(x, "bus")[x] \]

\[ \text{Connect}(x_1, "42", "85") \lor \text{Connect}("57", x_2, "85") \{ x_1, x_2 \} \]

\[ \forall y. p(x,y)[x] \]

**Answers depend on the interpretation domain, not just on the database contents**

First-order Logic Queries

**Definition**

An \( n \)-ary **first-order query** \( q \) is an expression \( \varphi[x_1, \ldots, x_n] \) where \( x_1, \ldots, x_n \) are exactly the free variables of \( \varphi \) (in a specific order).

**Definition**

An answer to \( q = \varphi[x_1, \ldots, x_n] \) over an interpretation \( I \) is a tuple \( \langle a_1, \ldots, a_n \rangle \) of constants such that

\[ I \models \varphi[x_1/a_1, \ldots, x_n/a_n] \]

The result of \( q \) over \( I \) is the set of all answers of \( q \) over \( I \).

Domain Dependence

We have defined FO queries over interpretations

\[ \neg \text{Lines}(x, "bus")[x] \]

\[ \text{Connect}(x_1, "42", "85") \lor \text{Connect}("57", x_2, "85") \{ x_1, x_2 \} \]

\[ \forall y. p(x,y)[x] \]

Answers depend on the interpretation domain, not just on the database contents
Natural Domain

First possible solution: the natural domain

Natural domain semantics (ND):
- fix the interpretation domain to $\text{dom}$ (infinite)
- query answers might be infinite (not a valid result table)
  $\Rightarrow$ query result undefined for such databases

Active Domain

Alternative: restrict to constants that are really used
$\Rightarrow$ active domain
- for a database instance $\mathcal{I}$, $\text{adom}(\mathcal{I})$ is the set of constants used in relations of $\mathcal{I}$
- for a query $q$, $\text{adom}(q)$ is the set of constants in $q$
- $\text{adom}(\mathcal{I}, q) = \text{adom}(\mathcal{I}) \cup \text{adom}(q)$

Active domain semantics (AD):
consider database instance as interpretation over $\text{adom}(\mathcal{I}, q)$

Query answers under natural domain semantics:
1. $\neg\text{Lines}(x, "bus")[x]$
   Undefined on all databases
2. $(\text{Connect}(x_1, "42", "85") \lor \text{Connect}("57", x_2, "85"))[x_1, x_2]$
   Undefined on databases with matching $x_1$ or $x_2$ in Connect, otherwise empty
3. $\forall y. p(x, y)[x]$
   Empty on all databases

Query answers under active domain semantics:
1. $\neg\text{Lines}(x, "bus")[x]$
   Let $q' = \text{Lines}(x, "bus")[x]$. The answer is $\text{adom}(\mathcal{I}, q) \setminus M[q'](\mathcal{I})$
2. $(\text{Connect}(x_1, "42", "85") \lor \text{Connect}("57", x_2, "85"))[x_1, x_2]$
   The answer is $M[\varphi_1](\mathcal{I}) \times \text{adom}(\mathcal{I}, q) \cup \text{adom}(\mathcal{I}, q) \times M[\varphi_2](\mathcal{I})$
3. $\forall y. p(x, y)[x] \Rightarrow$ see board
Equivalence of Relational Query Languages

The following query languages are equivalent:
- Relational algebra RA
- FO queries under active domain semantics AD
- Domain independent FO queries DI

This holds under named and under unnamed perspective.

To prove it, we will show:

$$RA_{\text{named}} \subseteq DI_{\text{unnamed}} \subseteq AD_{\text{unnamed}} \subseteq RA_{\text{named}}$$

Domain Independence

Observation: some queries do not depend on the domain

- $$\text{Stops}(x, y, "\text{true"})[x, y]$$
- $$(x \approx a)[x]$$
- $$p(x) \land \neg q(x)[x]$$
- $$\forall y.(q(x, y) \rightarrow p(x, y))[x, y]$$

In contrast, all example queries on the previous few slides are not domain independent

Domain independent semantics (DI):
consider only domain independent queries
use any domain $$\text{adom}(I, q) \subseteq \Delta^I \subseteq \text{dom}$$ for interpretation

How to Compare Query Languages

We have seen three ways of defining FO query semantics
$$\leadsto$$ how to compare them?

**Definition**

The set of query mappings that can be described in a query language $$L$$ is denoted $$QM(L)$$.

- $$L_1$$ is subsumed by $$L_2$$, written $$L_1 \subseteq L_2$$, if $$QM(L_1) \subseteq QM(L_2)$$
- $$L_1$$ is equivalent to $$L_2$$, written $$L_1 \equiv L_2$$, if $$QM(L_1) = QM(L_2)$$

We will also compare query languages under named perspective with query languages under unnamed perspective.

This is possible since there is an easy one-to-one correspondence between query mappings of either kind (see exercise).
Consider an AD query $q = \varphi[x_1, \ldots, x_n]$.

For an arbitrary attribute name $a$, we can construct an RA expression $E_{a, \text{dom}}$ such that $E_{a, \text{dom}}(I) = \{ \{ a \mapsto c \} \mid c \in \text{dom}(I, q) \}$.

For every variable $x$, we use a distinct attribute name $a_x$

- if $q = R(t_1, \ldots, t_m)$ with signature $R[a_1, \ldots, a_m]$ with variables $x_1 = t_{w_1}, \ldots, x_n = t_{w_1}$ and constants $c_1 = t_{w_2}, \ldots, c_k = t_{w_2}$,
then $E_{q} = \delta_{a_1 \ldots a_n \rightarrow a_1 \ldots a_n} ( \sigma_{a_1 = c_1}( \ldots \sigma_{a_k = c_k}(\ldots)))$
- if $q = (x \approx c)$, then $E_{q} = \{ \{ a_x \mapsto c \} \}$
- if $q = (x \approx y)$, then $E_{q} = \sigma_{a_x = a_y}(E_{a_x, \text{dom}} \bowtie E_{a_y, \text{dom}})$
- other forms of equality atoms are similar

Remainig cases:

- if $q = \pi_{a_1, \ldots, a_n}(q')$ for a subquery $q'[b_1, \ldots, b_m]$ with $\{ b_1, \ldots, b_m \} = \{ a_1, \ldots, a_n \} \cup \{ c_1, \ldots, c_k \}$, then $\varphi_q = \exists x_{c_1}, \ldots, x_{c_k} \varphi_q'$
- if $q = q_1 \bowtie q_2$ then $\varphi_q = \varphi_{q_1} \land \varphi_{q_2}$
- if $q = q_1 \lor q_2$ then $\varphi_q = \varphi_{q_1} \lor \varphi_{q_2}$
- if $q = q_1 - q_2$ then $\varphi_q = \varphi_{q_1} \land \neg \varphi_{q_2}$

One can show that $\varphi_q[x_1, \ldots, x_n]$ is domain independent and equivalent to $q$.

\[ RA_{\text{named}} \sqsubseteq DI_{\text{named}} \quad (\text{cont'd}) \]

\[ DI_{\text{named}} \sqsubseteq AD_{\text{named}} \]

This is easy to see:

- Consider an FO query $q$ that is domain independent.
- The semantics of $q$ is the same for any domain $\text{dom} \subseteq \Delta^T \subseteq \text{dom}$.
- In particular, the semantics of $q$ is the same under active domain semantics.
- Hence, for every DI query, there is an equivalent AD query.

\[ AD_{\text{named}} \sqsubseteq RA_{\text{named}} \]

Consider an RA query $q = \varphi[x_1, \ldots, x_n]$.

For an arbitrary attribute name $a$, we use a distinct attribute name $a_x$

- if $q = R(t_1, \ldots, t_m)$ with signature $R[a_1, \ldots, a_m]$ with variables $x_1 = t_{w_1}, \ldots, x_n = t_{w_1}$ and constants $c_1 = t_{w_2}, \ldots, c_k = t_{w_2}$, then $E_{q} = \delta_{a_1 \ldots a_n \rightarrow a_1 \ldots a_n} ( \sigma_{a_1 = c_1}( \ldots \sigma_{a_k = c_k}(\ldots)))$
- if $q = (x \approx c)$, then $E_{q} = \{ \{ a_x \mapsto c \} \}$
- if $q = (x \approx y)$, then $E_{q} = \sigma_{a_x = a_y}(E_{a_x, \text{dom}} \bowtie E_{a_y, \text{dom}})$
- other forms of equality atoms are similar

Remainig cases:

- if $\varphi = \neg \psi$, then $E_{\varphi} = (E_{a_1, \text{dom}} \bowtie \ldots \bowtie E_{a_n, \text{dom}}) - E_{\psi}$
- if $\varphi = \varphi_1 \land \varphi_2$, then $E_{\varphi} = E_{\varphi_1} \bowtie E_{\varphi_2}$
- if $\varphi = \exists y. \psi$ where $\psi$ has free variables $y, x_1, \ldots, x_n$, then $E_{\varphi} = \pi_{a_1, \ldots, a_n} E_{\psi}$

The cases for $\land$ and $\lor$ can be constructed from the above.

A note on order: The translation yields an expression $E_{\varphi}[a_1, \ldots, a_{k_3}]$. For this to be equivalent to the query $\varphi[x_1, \ldots, x_n]$, we must choose the attribute names such that their global order is $a_1, \ldots, a_{k_3}$. This is clearly possible, since the names are arbitrary and we have infinitely many names available.
How to find DI queries?

Domain independent queries are arguably most intuitive, since their result does not depend on special assumptions.

How can we check if a query is in DI? Unfortunately, we can’t:

**Theorem**

Given a FO query $q$, it is undecidable if $q \in \text{DI}$.

→ find decidable sufficient conditions for a query to be in DI

Safe-Range Queries

Let $\varphi$ be a formula in SRNF. The set $rr(\varphi)$ of range-restricted variables of $\varphi$ is defined recursively:

$r(r(t_1, \ldots, t_n)) = \{x \mid x \text{ a variable among the } t_1, \ldots, t_n\}$

$r(x \approx a) = \{x\}$

$r(x \approx y) = \emptyset$

$r(\varphi_1 \land \varphi_2) = \begin{cases} r(\varphi_1) \cup \{x, y\} & \text{if } \varphi_2 = (x \approx y) \text{ and } \{x, y\} \cap r(\varphi_1) \neq \emptyset \\ r(\varphi_1) \cup r(\varphi_2) & \text{otherwise} \end{cases}$

$r(\varphi_1 \lor \varphi_2) = r(\varphi_1) \cap r(\varphi_2)$

$r(\exists y. \psi) = \begin{cases} r(\psi) \setminus \{y\} & \text{if } y \in r(\psi) \\ \text{throw new NotSafeException()} & \text{if } y \notin r(\psi) \end{cases}$

$r(\neg \psi) = \emptyset$ if $r(\psi)$ is defined (no exception)

Safe-Range Queries

**Definition**

An FO query $q = \varphi[x_1, \ldots, x_n]$ is a safe-range query if $rr(SRNF(\varphi)) = \{x_1, \ldots, x_n\}$.

Safe-range queries are domain independent. One can show a much stronger result:

**Theorem**

The following query languages are equivalent:

- Safe-range queries SR
- Relational algebra RA
- FO queries under active domain semantics AD
- Domain independent FO queries DI
Tuple-Relational Calculus

There are more equivalent ways to define a relational query language

Example: Codd’s tuple calculus

- Based on named perspective
- Use first-order logic, but variables range over sorted tuples (rows) instead of values
- Use expressions like \( x : \text{From,To,Line} \) to declare sorts of variables in queries
- Use expressions like \( x.\text{From} \) to access a specific value of a tuple
- Example: Find all lines that depart from an accessible stop

\[
\{ x : \text{Line} \mid \exists y : \text{SID,Stop,Accessible} . (\text{Stops}(y) \land y.\text{Accessible} \approx \text{true} \land \exists z : \text{From,To,Line} . (\text{Connect}(z) \land z.\text{From} \approx y.\text{SID} \land z.\text{Line} \approx x.\text{Line}) \}
\]

Summary and Outlook

First-order logic gives rise to a relational query language

The problem of domain dependence can be solved in several ways

All common definitions lead to equivalent calculi

\( \Rightarrow \) “relational calculus”

Open questions:
- How hard is it to actually answer such queries? (next lecture)
- How can we study the expressiveness of query languages?
- Are there interesting query languages that are not equivalent to RA?
