Aims of the course

Obtain an understanding of key topics in database theory with a special focus on query formalisms:

- Relational data model
- Basic and advanced query languages
- Expressive power of query languages
- Complexity of query answering + some algorithmic approaches
- Modelling with constraints

Connect databases with other advanced topics in logic/KR/formal methods

Literature, prerequisites, related courses

  - Available at http://webdam.inria.fr/Alice/
  - Slight deviations in the lecture
  - Further literature will be given for advanced topics
- Prerequisites: basics of first-order logic, Turing machines, worst-case complexity
- Related courses at TUD:
  - Advanced Logic
  - Foundations of Semantic Web Technologies
  - Introduction to Logic Programming
  - Introduction to Constraint Programming
  - Datenbanken (Grundlagen)
  - Intelligent Information Systems
What is a database?

A Database Management System (DBMS) is a software to manage collections of data.

~ highly important class of software systems
~ major role in industry and in research
~ extremely wide variety of concepts and implementations

General three-level architecture of DBMS:

• **External Level**: Application-specific user views
• **Logical Level**: Abstract data model, independent of implementation, conceptual view
• **Physical Level**: Data structures and algorithms, platform-specific

In this lecture: focus on logical view for relational data model

**Basic functionality of DBMS:**

- Schema definition: specify how data should be logically organised
- Update: insert/delete/update stored data
- Query: retrieve stored data or information derived from it
- Administration: user rights management, configuration, recovery, data export, etc.

**Many related concerns:**

- Persistence: data retained when DBMS is shut down
- Optimisation: ensure maximal efficiency
- Scalability: cope with increasing loads by adding resources
- Concurrency: support many update and query operations in parallel
- Distribution: combine data from several locations
- Interfaces: APIs, query languages, update languages, etc.

In this lecture: schema, query languages, some optimisation

**Overview**

1. Introduction | Relational data model
2. First-order queries
3. Complexity of query answering
4. Complexity of FO query answering
5. Conjunctive queries
6. Tree-like conjunctive queries
7. Query optimisation
8. Conjunctive Query Optimisation / First-Order Expressiveness
9. First-Order Expressiveness / Introduction to Datalog
10. Expressive Power and Complexity of Datalog
11. Optimisation and Evaluation of Datalog
12. Evaluation of Datalog (2)
13. Graph Databases and Path Queries
14. Outlook: database theory in practice

See course homepage [⇒ link] for more information and materials

The Relational Data Model
Database = collection of tables

<table>
<thead>
<tr>
<th>Line</th>
<th>Type</th>
</tr>
</thead>
<tbody>
<tr>
<td>85</td>
<td>bus</td>
</tr>
<tr>
<td>3</td>
<td>tram</td>
</tr>
<tr>
<td>F1</td>
<td>ferry</td>
</tr>
<tr>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Stops:

<table>
<thead>
<tr>
<th>SID</th>
<th>Stop</th>
<th>Accessible</th>
</tr>
</thead>
<tbody>
<tr>
<td>17</td>
<td>Hauptbahnhof</td>
<td>true</td>
</tr>
<tr>
<td>42</td>
<td>Helmholtzstr.</td>
<td>true</td>
</tr>
<tr>
<td>57</td>
<td>Stadtgutstr.</td>
<td>true</td>
</tr>
<tr>
<td>123</td>
<td>Gustav-Freytag-Str.</td>
<td>false</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Connect:

<table>
<thead>
<tr>
<th>From</th>
<th>To</th>
<th>Line</th>
</tr>
</thead>
<tbody>
<tr>
<td>57</td>
<td>42</td>
<td>85</td>
</tr>
<tr>
<td>17</td>
<td>789</td>
<td>3</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Every table has a schema:
- Lines[Line:string, Type:string]
- Stops[SID:int, Stop:string, Accessible:bool]
- Connect[From:int, To:int, Line:string]

Database = set of tables

Let dom ("domain") be the (infinite) set of conceivable values in tables.

For simplicity, we drop the datatypes of database columns and assume that each column uses the same datatype that supports all values in dom.

Definition
- A relation schema $R[U]$ consists of a relation name $R$ and a finite set $U$ of attributes ($|U|$ is the arity of $R[U]$)
- A table for $R[U]$ is a finite set of functions from $U$ to dom
- A database instance $I$ is a finite set of tables

Note: we disregard the order and multiplicity of rows.

Tables are also called relation instances. The table with relation schema $R[U]$ in the database instance $I$ is written $R^I$.

Towards a formal definition of "table"

A table row has one value for each column
~ row = function from the attributes of the table schema to specific values

Example: The row

<table>
<thead>
<tr>
<th>SID</th>
<th>Stop</th>
<th>Accessible</th>
</tr>
</thead>
<tbody>
<tr>
<td>42</td>
<td>Helmholtzstr.</td>
<td>true</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

can be represented by the function:

$$f : \{\text{SID} \mapsto 42, \text{Stop} \mapsto \text{"Helmholtzstr."}, \text{Accessible} \mapsto \text{true}\}$$

Database = set of relations

Observation: Attribute names don't matter. Instead of the function

$$\{\text{SID} \mapsto 42, \text{Stop} \mapsto \text{"Helmholtzstr."}, \text{Accessible} \mapsto \text{true}\}$$

we could also use a tuple:

$$\langle 42, \text{"Helmholtzstr."}, \text{true} \rangle$$

Necessary assumption: Attributes have a fixed order.

Definition
- A relation schema $R[U]$ is defined as before
- A table for $R[U]$ is a finite subset of dom$^{<U}$
- A database instance $I$ is a finite set of tables

Recall that a subset of dom$^{<U}$ is just a $|U|$-ary relation. Sets of relations are also called relational structures.
Database = interpretation of first-order logic

Recall:
- First-order logic is based on predicate symbols with a fixed arity (we won’t need function symbols here)
- An interpretation $I$ of first-order logic is a pair $\langle \Delta_I, \cdot_I \rangle$:
  - $\Delta_I$ is a set (the domain of interpretation)
  - $\cdot_I$ maps $n$-ary predicates $p$ to $n$-ary relations $p^I \subseteq (\Delta_I)^n$

This is (almost) a database instance!

**Definition**
- domain of interpretation $\Delta_I = $ database domain $\text{dom}$
- predicate symbol = relation name
- interpretation of predicate symbol (if finite!) = table
- finite first-order logic interpretation = database instance

Visualising relations

Binary relations (sets of pairs) can be viewed as directed graphs.

Example:

<table>
<thead>
<tr>
<th>Source</th>
<th>Target</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>1</td>
<td>3</td>
</tr>
<tr>
<td>2</td>
<td>5</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
</tr>
<tr>
<td>3</td>
<td>4</td>
</tr>
<tr>
<td>4</td>
<td>3</td>
</tr>
<tr>
<td>5</td>
<td>3</td>
</tr>
</tbody>
</table>

Many binary tables in one graph? Use table name to label edges!

Database = set of facts

Another convenient way to write databases:
- Lines(85, "bus")
- Lines(F1, "ferry")
- Stops(42, "Helmholtzstr.", true)

**Definition**
- A fact is an expression $p(t_1, \ldots, t_n)$ where
  - $p$ is an $n$-ary predicate symbol
  - $t_1, \ldots, t_n$ are constant symbols

A database instance is a finite set of facts.

When interpreting these facts logically, their least model is again the database instance (viewed as a first-order logic interpretation).

Database = hypergraph

What to do with tables of arity $\neq 2$?

$\leadsto$ generalise graphs to hypergraphs

**Definition**
- A hypergraph is a triple $\langle V, E, \rho \rangle$, where
  - $V$ is a set of vertices
  - $E$ is a set of edge names
  - $\rho$ maps each edge name $e \in E$ to an $n$-ary relation $\rho(e) \subseteq V^n$

In other words: finite hypergraphs are databases.
Summary: the relational model

Relational databases are everywhere:
- sets of tables with named attributes (“named perspective”)
- sets of relations (“unnamed perspective”)
- first-order logic interpretations
- sets of logical facts (ground atoms)
- hypergraphs (and graphs as a special case)

. . . all restricted to finite sets

Important elements of the theory of relational databases are very widely applicable, also to many datamodels that are not the classical relational one (e.g., graph databases, RDF databases, XML databases).

The Relational Algebra

Relational Algebra Queries

Query language based on a set of operations on databases.
Each operation refers to one or more tables and produces another table
(we often simplify notation and write a table name rather than a table instance)

Main operations of the named perspective:
- Selection \( \sigma \)
- Projection \( \pi \)
- Join \( \bowtie \)
- Renaming \( \delta \)
- Difference \( - \)
- Union \( \cup \)
- Intersection \( \cap \)

Selection

“Find all bus lines”
\( \sigma_{\text{Type}=\text{bus}} \) Lines

“Find all connections that begin and end in the same stop”
\( \sigma_{\text{From}=\text{To}} \) Connect

Definition

The selection operator has the form \( \sigma_{n=m} \)

- \( n \) is an attribute name
- \( m \) is an attribute name or a constant value

Consider a table \( R^I \) for \( R[U] \).

- For \( m \) constant value: \( \sigma_{n=m}(R^I) = \{ f \in R^I \mid f(n) = m \} \)
- For \( m \) attribute name: \( \sigma_{n=m}(R^I) = \{ f \in R^I \mid f(n) = f(m) \} \)

This is only defined if \( U \) contains the required attribute names.
Renaming

“Find all lines that depart from an accessible stop”

Stops:

<table>
<thead>
<tr>
<th>SID</th>
<th>Stop</th>
<th>Accessible</th>
</tr>
</thead>
<tbody>
<tr>
<td>57</td>
<td>Stadtgutstr.</td>
<td>true</td>
</tr>
<tr>
<td>123</td>
<td>Gustav-Freytag-Str.</td>
<td>false</td>
</tr>
<tr>
<td>...</td>
<td>...</td>
<td>...</td>
</tr>
</tbody>
</table>

We need to join Stops.SID with Connect.From \( \rightarrow \) use renaming

\[
\pi_{Line}(\sigma_{Accessible=\text{true}}(\text{Stops} \bowtie \delta_{From,To,Line \rightarrow SID,To,Line(\text{Connect}))))
\]

Definition

The renaming operator has the form \(\delta_{a_1,\ldots,a_n \rightarrow b_1,\ldots,b_n}\) with all \(a_i\) mutually distinct attribute names, and likewise for all \(b_i\).

Consider a table \(R^I\) for \(R[U]\).

\[
\delta_{a_1,\ldots,a_n \rightarrow b_1,\ldots,b_n}(R^I) = \{f \circ g \mid f \in R^I \text{ and } g : \{b_i \mapsto a_i\}_{i \leq n}\}
\]

where \(f \circ g\) is function composition: \((f \circ g)(x) = f(g(x))\)
Table constants in queries

It is sometimes convenient to define constant tables in queries.

"Find all stops near Helmholtzstr. (SID 42), including Helmholtzstr."

$$
\delta_{\text{To} \rightarrow \text{StopId}}(\pi_{\text{To}}(\sigma_{\text{From} = \text{"42\"}} \text{Connect})) \cup \{\text{StopId} \mapsto 42\}
$$

One can generalise this to constant tables with more than one column or more than one table (no additional expressive power, see exercise).

Reachability

Generalising the previous example:

"Stops that are Helmholtzstr."

$$R_0 = \{\{\text{From} \mapsto 42\}\}$$

"Stops that are next to Helmholtzstr."

$$R_1 = \delta_{\text{To} \rightarrow \text{From}}(\pi_{\text{To}}(\text{Connect} \Leftarrow R_0))$$

"Stops at distance 2 from Helmholtzstr."

$$R_2 = \delta_{\text{To} \rightarrow \text{From}}(\pi_{\text{To}}(\text{Connect} \Leftarrow R_1))$$

Stops reachable from Helmholtzstr. with a short-distance ticket:

$$R_0 \cup R_1 \cup R_2 \cup R_3 \cup R_4$$

What about all stops reachable from Helmholtzstr.?

→ see upcoming lectures . . .

Summary and Outlook

The relational model is very versatile

Relational algebra allows us to define queries with operators

Many operators exist, not all are really needed (see exercise)

Open questions:

- What does this have to do with logic? (next lecture)
- How hard is it to actually answer such queries? (complexity)
- How can we study the expressiveness of query languages?
